Slavic Corpus and Computational Linguistics

Dagmar Divjak, Serge Sharoff, and Tomaž Erjavec

Abstract: In this paper we focus on corpus-linguistic studies that address theoretical questions and on computational linguistic work on corpus annotation that makes corpora useful for linguistic analysis. First we discuss why the corpus linguistic approach was discredited by generative linguists in the second half of the 20th century, how it made a comeback through advances in computing and was finally adopted by usage-based linguistics at the beginning of the 21st century. Then we move on to an overview of necessary and common annotation layers and the issues that are encountered when performing automatic annotation, with special emphasis on Slavic languages. Finally we survey the types of research requiring corpora that Slavic linguists are involved in worldwide, and the resources they have at their disposal.

> *After all, language does look different if you look at a lot of it at once.*

> (J. M. Sinclair)

1. Introduction

The Slavic languages provide a fertile ground for corpus-based and computational investigations. For one, the Slavic languages combined count more than 315 million speakers (Sussex and Cubberley 2006), who have produced and continue to produce massive amounts of data on a daily basis. The Slavic languages also display peculiar typological features, which make them more challenging from a computational perspective in comparison to other commonly studied languages of the Indo-European family. For example, due to the richness of their morphology, Slavic languages exhibit a relatively extensive freedom in word order in comparison to the Germanic and Romance languages. From a computational viewpoint, this property is challenging because it results in a greater data sparsity, i.e., there are considerably more surface realisations for a given underlying linguistic phenomenon, be it the number of forms a word can display or the number of places the subject or object

Journal of Slavic Linguistics 25(2): 171–198, 2017.

of a sentence can occupy relative to the verb. Take, for example, the number of morphological forms of a verb: if participial forms are counted, Russian transitive verbs yield about 80 different forms, while English verbs have at most 5 different forms. Another example concerns the increased number of surface patterns for such pairs as Verb-Direct Object, because the position of the Direct Object can be quite flexible. Therefore, sparsity needs adequate representation in computational research on Slavic languages. Yet the same morphological richness and regularity in inflection also impacts computational studies of Slavic languages positively: it is possible to predict with reasonable precision the Part-of-Speech (PoS) category and the syntactic function of word forms from their endings, something that is considerably more difficult to achieve in the Germanic and Romance languages. Finally, the high regard in which both linguistics and mathematics are held in Slavic countries has yielded remarkable results. One of the earliest examples of research with Slavic corpora is the seminal paper by Andrej Markov which concerned predictions of word sequences on the basis of *Eugene Onegin* (Markov 1913; Hayes et al. 2013). This study led to development of Markov models, which are commonly used in modern computational linguistics for predicting a linguistic phenomenon from the adjacent context.

Both corpus and computational linguists use corpora to study languages, but there are fundamental differences between and within the two groups. As Renouf (2005) put it: "Corpus linguistics is essentially an arts-based discipline, while computational linguistics has a mathematical heritage, and though the latter is now increasingly engaging in textual study, the approaches remain philosophically distinct." Yet even within the group of corpus linguists, some will use corpora to address theoretical questions, while others will turn to corpora to collect the data they need to produce an accurate description of a phenomenon, and others still are fascinated by how corpora should be compiled and structured to be representative of a population of language speakers and useful to a group of corpus users. The same difference can be observed within the computational linguistic community, where some researchers will use corpora to design and improve machine learning models that can provide insights into how language works, while others focus on solving practical problems (related to e.g., information retrieval or automatic translation) or on improving the corpus as a resource. In this paper we will focus on corpus-linguistic studies that address theoretical questions and on computational linguistic work that makes it possible to annotate corpora, thereby making them useful for linguistic work.

2. A Corpus-Linguistic Perspective

In this section we reflect on the essence of corpus linguistics. We discuss why and how the copus-linguistic approach was discredited by generative lin-

guists in the second half of the 20th century, how it made a comeback through advances in computing, and how it was adopted by usage-based linguistics at the beginning of the 21st century.

2.1. Chomsky vs. Corpus Linguistics

Corpus linguistics was discredited in the early 1950s by Noam Chomsky. From a theoretical point of view, he suggested that the corpus could never be a useful tool for the linguist because the linguist must model language competence rather than performance. A corpus is by its very nature a collection of externalised utterances—it contains performance data and is therefore a poor guide to modeling linguistic competence. A second major criticism was levelled at two—admittedly erroneous—assumptions that many early corpus linguists are said to have made (McEnery and Wilson 1999), i.e., that 1) the sentences of a natural language are finite and 2) the sentences of a natural language can be collected and enumerated. Chomsky countered that the only way to account for a grammar of a language is by a description of its rules—not by an enumeration of its sentences. Corpora are necessarily "finite and somewhat accidental" (Chomsky 1957: 17). The syntactic rules of a language, on the other hand, are finite but give rise to an infinite number of sentences.

To this day, Chomsky remains at odds with corpus linguistic approaches, even in their more recent guises, as becomes clear from excerpts of an interview with him (Andor 2004):

> Corpus linguistics doesn't mean anything. It's like saying suppose a physicist decides, suppose physics and chemistry decide that instead of relying on experiments, what they're going to do is take videotapes of things happening in the world and they'll collect huge videotapes of everything that's happening and from that maybe they'll come up with some generalizations or insights. Well, you know, sciences don't do this. But maybe they're wrong. Maybe the sciences should just collect lots and lots of data and try to develop the results from them. [...] We'll judge it by the results that come out. So if results come from study of massive data, rather like videotaping what's happening outside the window, fine—look at the results. I don't pay much attention to it. I don't see much in the way of results. My judgment, if you like, is that we learn more about language by following the standard method of the sciences. The standard method of the sciences is *not to accumulate huge masses of unanalyzed data and to try to draw some generalization from them*. The modern sciences, at least since Galileo, have been strikingly different. What they have sought to do was to *construct refined experiments which ask, which try to answer specific questions*

that arise within a theoretical context as an approach to understanding the world. [emphasis ours]

Although Chomsky was wrong implying that scientists do not draw generalizations from looking at massive amounts of data (the early astronomers made large numbers of detailed observations and modern astrophysicists very literally do "videotape what's happening outside the window," or on the sun, for that matter), he does make two relevant points here that have been debated in linguistic circles more generally: 1) the fact that disagreement exists about what corpus linguistics is—a theory, a discipline, or a method—as well as about the type of things a corpus linguist is interested in and 2) what information a corpus can contribute to (theoretical) linguistic inquiry. We would like to add a third issue that was not raised by Chomsky but that has been debated extensively over the past 10 years, i.e., the lack of awareness of and training in proper data handling techniques that is widespread among linguists using corpora

2.2. What is Corpus Linguistics? A Theory, a Discipline, or a Method?

A rather innocent announcement for a Bootcamp in Quantitative Corpus Linguistics, posted on August 12, 2008, to the Corpora List,[1] sparked a discussion that continued for nearly three weeks and revealed a deep divide within the corpus linguistic community: disagreement exists about whether corpus linguistics is or should be a theory, a discipline, or a method. We will consider each of the options in turn.

2.2.1. A Corpus-Theoretical Approach

A theory is a system of ideas intended to explain something. Ideally, a theory is based on general principles independent of the phenomenon to be explained. The corpus-theoretical approach rests on the cyclical principle of minimal assumptions. Such a theory is constantly in the making and develops according to the requirements of the data. A corpus-theoretical approach would rely on what Tognini-Bonelli (2001) termed "corpus-driven" work, as opposed to work that is merely "corpus-based."

Corpus-based approaches bring models of language which are believed to be fundamentally adequate to the analysis and analyse the corpus data through these categories. Examples of such categories are things that most linguists take for granted, such as words or parts of speech. *Corpus-driven* approaches derive linguistic categories systematically from the recurrent pat-

[1] http://mailman.uib.no/public/corpora/2008-August/007064.html

terns and the frequency distributions that emerge from language in context. Linguists should only accept parts of speech to the extent that the data they are examining support these distinctions. Here, the question arises of how practical such an extreme data-driven approach is: does querying everything, time and again, really make for better analyses? Mahlberg (2005: 32) proposed, by way of compromise, that "[f]or the time being, a corpus linguistic theory seems to be best regarded as the rationale that governs the investigation of data and that determines how the results of the investigation are accommodated within a language description."

There is also a third strand, so-called *corpus-illustrated* work (Tummers et al. 2005), which subjects examples extracted from corpora to a largely traditional introspective analysis and does not require statistical analysis. Currently, the bulk of corpus linguistic work on Slavic languages takes this third approach.

2.2.2. Corpus Linguistics as a Discipline

A discipline is an area of study and a branch of learning that has developed a terminology and methodological conventions for the study of something and has accumulated a body of knowledge, stored and accessible in the form of published inventories, analyses, and descriptions.

Over the past 30 years, corpus linguistics has, no doubt, established itself. There are now plenty of conferences, journals, book series, and discussion lists where the results of corpus linguistic studies are presented. Thus we have the biennial Corpus Linguistics conference held since 2001 in the UK, or its American counterpart, the conference of the American Association for Corpus Linguistics, that has been held since 1999. Several publishers offer corpus linguistics journals, e.g., the oldest journal, ICAME, has been around since 1978. The *International Journal of Corpus Linguistics* has been published by John Benjamins since 1996, *Corpus Linguistics and Linguistic Theory* since 2005 by De Gruyter, and *Corpora* has been published by Edinburgh University Press since 2006. Many publishing houses also offer book series devoted to corpus linguistics, e.g., *Studies in Corpus Linguistics* by John Benjamins and *Language and Computers: Studies in Practical Linguistics* from Brill list more than 75 titles each. Finally, the Corpora List brings together all researchers interested in developing or using corpora. But does this make corpus linguistics a proper discipline? Renouf (2005) aptly states that, as a discipline, corpus linguistics would still be "an amalgam of great precision and best endeavours; a somewhat undisciplined discipline. Yet as a branch of empirical study, this is ultimately its purpose, for empiricism precludes any a-priori assumptions."

2.2.3. Corpus Linguistics as a Method

Could corpus linguistics be a method then? And what would this method achieve? Chomsky even doubted that corpus studies would qualify as method. In his opinion corpus linguistics is like observing the tides:

> If you want to use hints from data that you acquire by looking at large corpuses [sic], fine. That's useful information for you, fine. I mean, Galileo might have gotten some hints from looking at events that were happening in the world. In fact, he did. He observed the tides—that's like corpus linguistics. You're observing the tides. (Andor 2004: 99)

But this picture reveals a stubborn misconception: corpus linguists do not merely observe. Yes, corpus linguists select a random sample from a representative and balanced collection of texts that represent one or more varieties of the language they are studying. They stick to that sample and are not allowed to include additional examples that would nicely illustrate their point, nor to remove examples that disprove their account. Traditionally, this object of study is typically presented in the form of KWIC (keyword in context) concordance lines, and this presentation inclines the researcher to scan the item serially within an ordered, usually alphabetical, context. But at the heart of a corpus-based study lies the (often still manual) annotation of examples. In order to annotate data in a verifiable way, the corpus linguist needs to operationalize linguistic parameters so that they can be applied consistently to a large number of examples. This introduces rigour and objectivity into the analysis and makes it possible to feed the annotated sample into a computer for statistical analysis.

Unfortunately, corpus linguistics remains (or used to remain) silent on the mechanics underlying this process: there is no specific convention for matching a hypothesis against textual reality, or vice versa, or even a requirement for an articulated hypothesis. Corpus linguistics does not espouse particular statistical methods or demand statistical rigour, even though some statistical measures (e.g., relative frequency, chi-square) are commonly applied (Renouf 2005).

Is there a way in which we could move from (as Chomsky put it) "accumulat[ing] huge masses of unanalyzed data and try[ing] to draw some generalization from them" to using corpus linguistic methods to "answer specific questions that arise within a theoretical context as an approach to understanding the world"? This is the question we explore in Section 2.3.

2.3. Corpus Linguistics and Linguistic Theory

Over the past 10 to 15 years, there has been a successful rapprochement between corpus linguistics as a method and usage-based theoretical approaches such as cognitive linguistics.

Cognitive linguistics (henceforth CL) is a usage-based model of language structure (Langacker 1987: 46), a "data-friendly" theory, with a focus on the relationship between observed form and meaning. CL rejects that idea that language is innate and imposed top-down by Universal Grammar, but instead explores the hypothesis that language is built bottom-up, from exposure to actual usage. Cognitive linguists do not make a distinction between competence and performance: all aspects of grammatical knowledge are derived from the language users' experience with frequent strings of concrete linguistic expressions.

2.3.1. Frequency and Usage-Based Linguistic Theory

Corpora are very attractive sources of data for linguists working in the usage-based tradition, and the probabilistic turn was influenced by the rise of corpus linguistics and the development of new statistical and computational tools for the analysis of quantitative data.[2] Corpus linguists are not interested in the frequency of sentences; they look for frequencies of patterns (Stefanowitsch 2005: 295). Corpora give access to form frequency and distribution in naturalistic settings. Frequency is among the most robust predictors of human performance (Hasher and Zacks 1984), and human beings extract frequency information automatically from their environment. Therefore they can use statistical properties of linguistic input to discover structure, including sound patterns, words, and the beginnings of grammar (Ellis 2002). The ability to extract the distributional characteristics of natural language plays a key role in linguistic development. What we learn may well be a probabilistic grammar grounded in our language experience. The strong influence of frequency on processing supports a dynamical model of grammar. The frequency with which linguistic forms are experienced forms the core of our grammatical knowledge. In other words, the ability of humans to extract patterns could circumvent the need for environmental linguistic triggers to set parameters specifying a fixed set of mutually exclusive linguistic properties, as generative grammar assumes.

[2] Note that proponents of the "corpus as a theory" do not consider this a happy marriage: "For cognitive linguists, meaning is in the individual, monadic minds of speakers and hearers; for corpus linguists, meaning is in the discourse (or the corpus, as a sample thereof)" (Teubert, 14 August 2008, Corpora List).

2.3.2. Corpora and the Form-Meaning Relationship

Usage-based linguistics thus provides corpus linguists with a theoretical framework that generates hypotheses that can be tested against corpus data, and this is particularly relevant for colleagues working on Slavic languages. As Divjak, Kochańska, and Janda (2007) argued, from its early days, cognitive linguistics has attracted the attention of linguists with research interests in Slavic languages, such Cienki (1989), Dąbrowska (1997), Janda (1986), and Rudzka-Ostyn (1992). This is not surprising for at least two reasons. Politics have played a crucial role in bringing the Slavic linguistic tradition and the cognitive paradigm closer. The Cold War era was the time when East European linguists in general and Russian linguists in particular were largely isolated from theoretical discussions in the West, due in part to the political writings of Chomsky, which led to his entire oeuvre being censored. As a consequence East European linguists were never forced to experiment with autonomous theories of language but rather maintained focus on the form-meaning relationship and how it is embedded in the larger reality of human experience. Some of their theories and models became known in the West. These include the Russian Meaning↔Text framework, first developed by Mel'čuk (1988) in Moscow and the natural semantic metalanguage theory formulated by Wierzbicka (see Wierzbicka 1972 for the first book-length treatment).

Most of the work done in Eastern Europe, however, never made it to the other side of the Iron Curtain. This is all the more regretful since one of the founding assumptions of cognitive and functional linguistic theories that are current in the West has been present in Slavic linguistics all along; Slavic linguists have always recognized the fundamentally symbolic nature of language and hence the fact that diverse formal aspects of language exist for the purpose of conveying meaning. Another, and very vigorous tradition of formal and then computational research on Slavic languages, is the Prague tradition with its attention to linking the form, which is computationally tractable, to its function, which needs to be inferred (Sgall 1995). On the basis of this functional syntax theory, a large syntactically annotated corpus, the Prague Dependency Treebank, was manually annotated (Hajičová 1998; Hajič 1998) and used in various studies, as well as a number of other annotated corpora and tools for processing different registers of the Czech language.

2.3.3. Linguists and Data Handling

Unfortunately, linguists, including those taking a corpus-based approach, have been lacking in data handling hygiene.

For one, they have not been very concerned about *formulating hypotheses to test their theory* (Divjak 2015; Dąbrowska 2016). Yet we need to formulate

hypotheses, derive testable predictions from our hypotheses, carry out the tests, and use the results to refine the hypotheses—and the theory—when necessary. This is part and parcel of the scientific cycle (Kuhn 1962) and corpora offer unrivalled opportunities to test theoretical hypotheses on naturally occurring data.

Early corpus linguistics required data processing abilities that were simply not available at that time and quantitative insights that had not yet spread beyond the sciences. But it wasn't until the turn of the century that the principle of total accountability took hold in corpus linguistic work, and researchers started to respect the requirement to look at all available examples, not just cherry-picking the ones that looked most convincing for their argumentation. Typically, the corpus was (and often still is) considered a repository of examples, and there is no systematic approach to addressing all the evidence. Arnold et al. (2000) were among the first to analyze post-verbal word order variation in English across the total set of instances from the corpus search, and the results were subjected to quantitative analysis (significance testing, correlation, and regression). Over the past 15 years, tremendous progress has been made, and more and more studies are being published that respect the principle of total accountability. With this, the insight has come that raw frequencies are not in and of themselves, or directly, of any scientific interest. While as recently as 10 years ago the fact that quantitatively sophisticated corpus-based argumentation was required remained something for which the case had to be made (cf. the discussion about the observed-frequency fallacy versus the expected frequency epiphany (Stefanowitsch 2005: 296)), we can now speak of a quantitative turn.

Janda (2013) presents a unique selection of seminal articles that together have brought about the quantitative turn in cognitive linguistics. But we can go further still: Milin et al. (2016) recently made the case we must rely on modeling techniques that are based on biologically and psychologically plausible learning algorithms if we are to use a quantitative approach to advance our understanding of how knowledge of language emerges from exposure to usage.

To sum up, the criticisms that Chomsky leveled against using corpora for linguistic research have been addressed by the corpus linguistic community, and by cognitively and functionally minded corpus linguists in particular. They have shown how corpus data can be used (to quote Andor's Chomsky interview again) to "construct refined experiments which ask, which try to answer specific questions that arise within a theoretical context as an approach to understanding the world." Of course, this work would not have been possible without large collections of text that are annotated with relevant information. The automatic annotation of text collections is one of the core tasks of computational linguistics.

3. A Computational Perspective

Many computational linguistic tasks can be seen as a process of text annotation. Such tasks are especially relevant for corpus linguistics as they result in corpora that are annotated with linguistic information that can be then profitably used in further linguistic research. This section, therefore, gives an overview of the necessary and most commonly encountered annotation layers and the issues that crop up when performing automatic annotation, with special emphasis on Slavic languages. We start, however, with an excursus on how the need for large annotated text collections arose.

3.1. Rules vs. Machine Learning

Up until the 1990s the computational processing of languages, including Slavic, was based on a system of rules. The rule-based approach was, especially in the U.S. following Chomsky's lead, primarily applied to syntax while in Europe, including the Slavic speaking countries, this approach was more evident in computational formalisms for morphological analysis. These were typically based on finite-state methods and their implementations, such as Intex (Silberztein 1993), with manually constructed rules, e.g., to derive all acceptable surface forms for a set of lemmas (Vitas et al. 2003) or to generate possible interpretations of a given word form. A Russian word form such as *duša* can have several interpretations, i.e., the nominative case of a feminine noun ('soul'), the genitive case of a masculine noun ('shower'), or the gerund form of a verb ('strangle').

With more data becoming available in electronic form, towards the end of the 1990s the dominant rule-based paradigm shifted towards the use of machine learning (ML) (Manning and Schütze 1999), i.e., a set of methods to find and exploit regularities in the data. In the case of supervised ML, this procedure is based on existing—typically manually inserted—annotations on the desired level of linguistic description. For example, instead of a linguist formulating syntactic rules, a ML method can detect statistical patterns in a large number of manually annotated sentences, such as the patterning of the PoS tags of words, and produce a model for their automatic annotation. Some ML methods produce weighted or ordered rules that can be inspected (e.g., decision trees), while others, and these are now becoming the majority, are, to a greater or lesser degree, "black box" systems, with the models being very large matrices of statistical values over combinations of the defined features. Such systems are very useful in practice as they can be used to automatically annotate corpora or texts, i.e., they are used as language technology tools for applications such as PoS tagging, parsing, or machine translation. It is also possible to draw statistical inferences without a manually annotated

corpus, by using unsupervised machine learning. An early example of this approach for linguistic purposes is Biber's multidimensional analysis (Biber 1988), which detects statistically significant grouping of features, such as the greater number of noun phrases and nominalizations vs. the use of personal pronouns and stance verbs.

The focus on developing tools for annotating (Slavic) languages has thus moved from manually developing rules (grammars) and lexica for their processing to manually annotating corpora with the phenomenon under investigation and relying on combinations of largely generic ML methods. Still, to engineer the required features for the problem and find the optimal set of parameters for training the model, linguistic insight into the problem is necessary.

Current ML methods can, for most annotation tasks, already take into account much more contextual information than manually constructed rules ever could. For example, rule-based machine translation systems were much less successful in dealing with ambiguities in language when compared to the current ML-based approaches, since too many fairly subtle rules are needed for resolving the ambiguities, while statistical MT easily "plagiarizes" a large number of translation examples. A rule-based approach needs a lot of information to translate ambiguous words, e.g., *konek* in Russian as 'small horse', 'skate', 'seahorse', 'hobby' or 'roof ridge', while a statistical MT can efficiently memorize the most frequent contexts of use. Another reason for their success is that ML methods are largely language-agnostic, so a working model can be built from nothing but a large number of examples (Sharoff and Nivre 2011).

3.2. Part-of-Speech Tagging

One of the early applications of computational linguistics is the automatic detection of morphosyntactic properties of words in text (Nikolaeva 1958; van Halteren 1999). This task is commonly known as Part-of-Speech (PoS) tagging, mainly because it was first developed for English, where the main problem is to disambiguate between the PoS of words in context, e.g., to determine whether "walk" in "He likes to walk" or "He took a walk yesterday" is a verb or a noun. While typical English PoS tag sets also take into account some other lexical (e.g., common or proper noun) and inflectional (e.g., singular or plural) properties of words, English, as an inflectionally poor language, has only a few of the latter, so the tag sets for English, as well as for most Western European languages, are rather small, with about 20–100 different tags, e.g., NN for singular common nouns, NNS for plural, etc.

The situation is quite different for the Slavic languages, where all the morphosyntactic properties are typically encoded in the tag sets. In the multilingual MULTEXT-East specifications (Erjavec 2012), the Slavic languages (apart from Bulgarian and Macedonian) have a tag set of over 1,000 PoS tags

to cover different inflectional categories. Given the wealth of information encoded in tag sets covering Slavic inflections, it is better to call such tags morphosyntactic descriptions (MSDs), a practice we adopt in this paper. While English typically has used "synthetic" tags, where each tag has a legend explaining what it means, a more structured approach is needed for the large Slavic MSD tagsets. A commonly used approach, first proposed in the EAGLES (Expert Advisory Group on Language Engineering Standards) project (EAGLES 1996), is to use a position-based encoding, where each attribute is given a position in the MSD string and its value is a character, with the specifications giving the mapping between attribute-value pairs and their encoding. So, for example, the MULTEXT-East specifications have the MSD `Vmen` corresponding to the feature-structure `Verb, Type=main, Aspect=perfective, VForm=infinitive`. Some approaches then dispense with the MSD tagsets altogether and only retain the features. The latest and most important development in this respect is the Universal Dependencies (UD) project (Nivre et al. 2016), which seeks to cover all languages, not only for morphosyntax, but also for dependency syntax.

As with other levels of annotation, in order to automatically tag a corpus with PoS tags or MSDs, modern approaches rely on machine learning. To train a tagger for a new language, three components are usually required:

1. a training corpus in which each word is marked with its morphosyntactic features in a given context; the following Slovenian example can be represented as:[3]

   Dogodek v Ankaranu je bila dramatična nesreča.
   'The event in Ankaran was a dramatic accident.'

Form	**Lemma**	**UD PoS**	**MSD**	**UD features**
Dogodek	dogodek	NOUN	Ncmsn	Case=Nom, Gender=Masc, Number=Sing
v	v	ADP	Sl	Case=Loc
Ankaranu	Ankaran	PROPN	Npmsl	Case=Loc, Gender=Masc, Number=Sing
je	biti	AUX	Va-r3s-n	Mood=Ind, Negative=Pos, Number=Sing, Person=3, Tense=Pres, VerbForm=Fin
bila	biti	VERB	Va-p-sf	Gender=Fem, Number=Sing, VerbForm=Part
dramatična	dramatičen	ADJ	Agpfsn	Case=Nom, Degree=Pos, Gender=Fem, Number=Sing
nesreča	nesreča	NOUN	Ncfsn	Case=Nom, Gender=Fem, Number=Sing
.	.	PUNCT	Z	

[3] From the Slovenian Universal Dependencies Treebank Version 1.4, http://hdl.handle.net/11234/1-1827

2. a separate lexicon with compatible morphosyntactic annotations to cover cases not present in the training corpus; for example:

Ankarana	Ankaran	PROPN	Npmsg	Case=Gen, Gender=Masc, Number=Sing

3. a tool for building disambiguation models from such annotations, for example, for learning that the elements of noun phrases agree in case, number and gender:

dramatična	dramatičen	ADJ	Agpfsn	Case=Nom, Degree=Pos, Gender=Fem, Number=Sing
nesreča	nesreča	NOUN	Ncfsn	Case=Nom, Gender=Fem, Number=Sing

The machine learning frameworks for PoS tagging learn the probabilities of sequences of tags in the traditional taggers (Brants 2000; Schmid 1994) or the matches between the morpho-syntactic features in their more modern versions (Müller et al. 2015). For example, in the Russian example of *duša* discussed above, the context provides sufficient information to choose the right interpretation via the sequence of probabilities:

> U nego preobladaet ne intelekt, a duša. (coordination of two nominative cases)
> 'For him, reasoning is more important than soul.'
>
> Nel'zja bylo pomyt'sja posle igry iz-za otsutstvija duša. (genitive often follows a noun)
> 'It was impossible to wash after the game since there were no showers.'
>
> Vragi katalis' po zemle, duša drug druga. (availability of a direct object)
> 'The enemies rolled around on the ground, trying to strangle each other.'

4. Research Activity

In this section we survey the types of research requiring corpora that Slavic linguists are involved in worldwide and the resources they have at their disposal.

4.1. Self-Reported Data on Research Activity Based on Corpora

Overall, linguistic research for the Slavic languages that relies on corpora is well-represented. The information we received in response to our survey, posted on the Corpora list July 2016, is visually summarized on the map in Figure 1. The size of the dots is proportional to the number of linguists who filled out the survey. The U.S. is not pictured due to space constraints. In total, linguists from 28 different countries responded. Countries with 5 or more responses are listed in Table 1.

Three linguists each from Slovenia and the U.K. (excluding the current authors) self-reported, two each from Austria, Canada, Italy, Slovakia, and Ukraine, and one each from Belarus, Denmark, Finland, France, Georgia, Ireland, Macedonia, Romania, Serbia, and Switzerland.

However, it should be stressed that this is self-reported data. The fact that a country is not represented does not mean that it does not employ corpus or computational linguists, and the numbers reported are not official counts.

Overall, three types of research are being conducted:

1. **Computational linguistic research**, focusing on compiling corpora (historical and contemporary; individual, comparative, parallel; translation; learner) and developing the NLP tools to annotate and mine them morphologically, syntactically, and semantically (treebanks, ontologies, wordnet, word sense disambiguation, construction identification); machine translation; information retrieval; sentiment analysis; topic modeling;
2. **Linguistic research that uses corpora** as sources of authentic examples in a wide variety of domains from the core areas of linguistics (morphology, syntax, semantics) branching out into discourse-pragmatics (politeness, anaphora resolution) and sociolinguistics (including dialectology, language variation and change); historical linguistics (grammaticalization); cultural linguistics; bilingualism (and language contact); and teaching methodology;
3. **Quantitative corpus-based studies within a usage-based framework**, mostly study of "rival forms," variation of some kind, and phenomena that resist being captured by a rule. Very few respondents work within a formal framework (LFG, HPSG, or generative grammar; semantics, pragmatics). Chomsky's spell still binds some.

In the next sections we focus on the last category, the quantitative corpus-based studies within a usage-based framework because it is this type of work that best rebuts Chomsky's criticism.

It is interesting to note that corpus and computational linguists appear to have focused on morphology and syntax, quite possibly because these levels of analysis are more faithfully rendered in text. Other levels of analysis, such

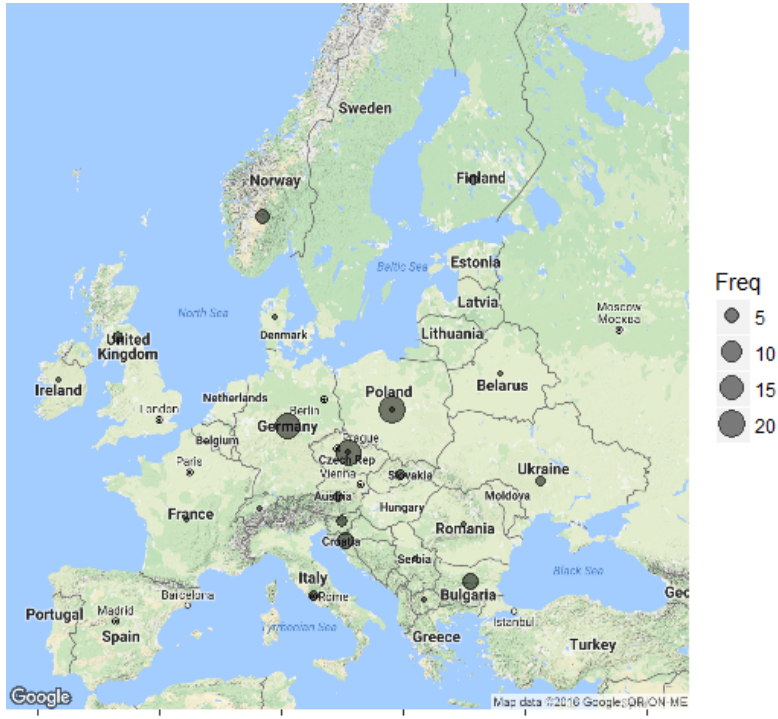

Figure 1. Map depicting number of (self-reported) corpus linguists working on Slavic language across Europe. The dots are proportional to the number of linguists who filled out the survey per country.

Table 1. Countries with 5 or more self-reported corpus or computational linguists.

Country	**Number of self-reported corpus and computational linguists**
Poland	21
Czech Republic	19
Germany	18
USA	14
Russian Federation	13
Bulgaria	6
Croatia	5
Norway	5

as phonology and pragmatics, however, are now receiving attention due to an increased interest in speech recognition and sentiment analysis.

4.2. Corpus Linguistics Studies

We will highlight a few strands of research that use corpus linguistic methods (to quote Chomsky again) to "answer specific questions that arise within a theoretical context as an approach to understanding the world" (Section 4.2.1.) and to do so in a methodologically sound way that introduces new techniques into the field (Section 4.2.2). Because of this, these studies have found resonance outside the domain of Slavic linguistics in which they originated. Interestingly, the overwhelming majority of these studies relies on insights from cognitive linguistics. As noted above, cognitive linguistics is a data-friendly theory, and as such, ideally suited to be tested against data from corpora. In Section 4.2.3 we will review work that bridges the gap between corpus and computational linguistics.

4.2.1. Answering Theoretical Questions

Work by Divjak (2003a/b) focused on capturing how verbs are used in context to determine their exact meaning and distinguish between even the most semantically similar words, such as near-synonyms. Some of these studies are described in Section 4.2.2. Here we will focus on the fact that these studies put behavioral profiles (BP) (Divjak 2006; Divjak and Gries 2006) on the corpus linguistic agenda and spawned diverse types of studies on linguistic profiling.

The BP studies start from two basic assumptions rooted in cognitive linguistics. On the one hand, all levels of linguistic analysis—morphology, syntax, and semantics—are expected to convey meaning and are, therefore, potentially relevant for determining a word's lexical core. Because of this, until more knowledge has accumulated, we should not focus a priori on one level, e.g., co-occurrence semantics, discarding the other levels. The effects of incorporating one or more levels in the analysis were illustrated in Divjak (2006). On the other hand, all annotation should be naive, that is, directly accessible to speakers and should not require linguistic abstraction. For example, BPs do not expect native speakers to be able to identify an inanimate subject or a past tense, but they do expect them to know whether something is alive or whether an event has already happened. In the annotation the linguistic labels (e.g., "past tense") corresponding to the experience (of an event that has happened) were used, but merely as shorthand; no linguistic knowledge on the part of the speaker is implied. That is, speakers do not need to be able to label something as past tense to be sensitive to the experience of "pastness."

Members of the CLEAR group at the University of Tromsø in Norway[4] have focused on individual dimensions of the BP. Solovyev and Janda (2009) analyzed 500 corpus sentences for each of six Russian synonyms for 'sadness' and five synonyms for 'happiness'. They annotated the dataset with properties capturing the nouns' *constructional profiles*. More concretely, they tracked the statistical distribution of case marking on the noun and the presence (or absence) of prepositions. Their data revealed that each noun has a unique constructional profile.

Janda and Lyashevskaya (2011) analyzed verbs in terms of their *grammatical profiles*, the "relative frequency distribution of the inflected forms of a word in a corpus" (Janda and Lyashevskaya 2011: 719). In their study they collected data on the distribution of Tense-Aspect-Mood (TAM) across 1,575 pairs of verbs, representing 5,951,250 verb forms in the Russian National Corpus (RNC). The result show that there is a strong attraction between certain lexical items and specific constellations of TAM markings and that this attraction is motivated semantically. Their study also contributed to an important general discussion in corpus methodology, i.e., the level of granularity at which annotation should be carried out, concluding that the appropriate level is determined by the language and the linguistics phenomenon under scrutiny. Grammatical profiles have been used extensively in historical linguistic work as well (Eckhoff and Janda 2014; Nesset, Janda, and Eckhoff 2014a/b).

Janda and Lyashevskaya (2013) explore the power of *semantic profiles* to test the hypothesis that Russian verbal prefixes express meaning even when they are used to create a purely aspectual pair. This contradicts the traditional assumption that prefixes in this function are semantically empty. Relying on the semantic tags provided by the RNC, they analyze 382 perfective partner verbs with *po-*, *s-*, *za-*, *na-* and *pro-*, five of the most common verbal prefixes in Russian. They found evidence of a significant relation between semantic tags and prefixes and were able to pin down the meaning of each prefix by relying on the semantic tags it attracts or repels. This confirms their hypothesis that verbs choose the prefix that best fits their lexical meaning when forming a perfective counterpart.

Kuznetsova (2015) presents an overview of studies in linguistics profiling, including diachronic profiles. As Kopotev, Lyashevskaya, and Mustajoki (2018) conclude, "the list of profiling types can be easily continued if we take into account word order, syntactic and semantic roles, narrator's viewpoint or any other kind of linguistic features." But early BP studies intentionally refrained from separating out the dimensions in order to establish whether corpus data can be used as a shortcut to a cognitively realistic representation of language knowledge. Analyzing the morphology, syntax, semantics, pragmatics separately is something that may suit linguists, but there is no proof

[4] https://en.uit.no/forskning/forskningsgrupper/gruppe?p_document_id=344365

that this is the approach taken by speakers of a language. Hence caution is needed when a dimensional approach is taken within a cognitive linguistic framework.

4.2.2. Introducing Statistical Techniques to the Field

Much of the methodological progress made in the analysis of corpus data involves the use of ever more advanced statistical techniques. The use of binary logistic regression is well-attested in Slavic corpus linguistics, for example in Sokolova, Lyashevskaya, and Janda (2012). It is explained in more detail in the chapter on cognitive linguistics by Laura Janda and Stephen M. Dickey (this volume). The idea of "rival forms" is one that permeates morphological work on Slavic languages as well. The morphological richness these languages display has yielded an abundance of choice in certain places. Questions of what might motivate native speakers in choosing between two options are something that corpus linguistic approaches are particularly well-suited to answer.

In collaboration with the quantitative linguist R. Harald Baayen, Slavic linguists have explored and compared a number of statistical techniques to predict which of a number of forms, typically two, will be chosen given a range of properties (Baayen et al. 2013). Choices between more than two options are possible, and again Slavic linguists were among the first to do so. The choice between six near-synonyms expressing TRY was modelled using polytomous logistic regression (Divjak 2010a). This study, too, is described in more detail in the chapter on cognitive linguistics by Janda and Dickey.

Possibly due to the complexity of the languages they analyze, linguists working on Slavic languages have been instrumental in embedding statistical analysis techniques within corpus linguistics and in expanding the range of techniques used. Importantly, Slavic linguists turned to more sensitive models early on. Divjak turned to mixed effects binary logistic regression to study the relationship between aspect and modality in modal chunks of the type "modal word + infinitive" in Russian (Divjak 2009) and Polish (Divjak 2010b) in a custom-made million-word parallel corpus, now part of the Parallel Corpus of Slavic and Other Languages (http://www.slavist.de/). The results of this study confirm that the general linguistic hypothesis linking perfective aspect to deonticity needs reversing for Russian, where the imperfective goes hand in hand with deonticity, while the perfective favours dynamicity. In addition, it was found that the relation between aspect and modality is mediated by a variable that outperforms even the reversed hypothesis in predicting aspectual choice in modal contexts. The meaning of this variable, state of affairs applicability (generic vs. specific), predicts aspectual choice in modal constructions better than the lexical meaning of modality (dynamic vs. deontic) since the concepts captured by the 'generic vs. specific' parameter are an abstraction of the major constraints on aspectual form in Russian.

Mixed-effects modeling was also applied by Janda, Nesset, and Baayen (2010) to study an ongoing suffix shift in Russian verbs, a diachronic change in which the suffix *-a* is being replaced by the productive suffix *-aj*. Corpus data show that the Russian suffix shift is not taking place uniformly. Using insights from cognitive linguistics, Janda, Nesset, and Baayen (2010) approached the paradigm as a prototypical category with center and periphery and found evidence for the fact that the peripheral forms of a paradigm, such as the gerund, are more affected by language change than the prototypical forms, such as the third person singular, which is insulated from change. In both studies mixed-effects modeling served as a tool to take the complex interdependencies in language data into account, such as multiple observations per author, per word, or per paradigm, which results in more reliable inferential models.

4.2.3. Bridging the Gap between Corpus and Computational Studies

Recently a series of studies has appeared that bridges the gap between corpus and computational work; that is, work that uses computational linguistic techniques to extract data from corpora and answer specific linguistic questions. The needle-in-a-haystack method (NHM), elaborated by Fidler and Cvrček, provides a quantitative method for text analysis. Fidler and Cvrček (2015), for example, use corpus-linguistic methods to examine the relationship between language usage patterns and divergence in text interpretation in Czech. They analyse a set of texts (Czechoslovak presidential New Year's addresses from 1975 to 1989) and contrast the texts statistically with corpora from two different periods: one from the totalitarian period and the other from the contemporary (post-totalitarian) period. The comparison was based on the difference index, an effect-size estimator, which was used to enhance the interpretation of keyword analysis outcomes. The two analyses yield significantly different results: the data from the analysis using the contemporary corpus were commensurate with contemporary readers' impressions; those from the analysis using the totalitarian corpus fluctuated in tandem with (and sometimes in anticipation of) political and social changes during the 15-year period and suggested an interpretation of the texts by a reader more familiar with totalitarian texts.

5. Language Resources

The term "language resources" refers to any digital language data—in particular various types of language corpora and lexicons—that can be, inter alia, used for research on language. Such resources are the basis for corpus linguistics, but these resources must be, to be truly useful, made available to other researchers. This has long been the case for large, national reference corpora,

typically automatically annotated with MSD tags and lemmas, which are available for a number of Slavic languages, e.g., the Russian National Corpus (Sharoff 2005),[5] the National Corpus of Polish (Przepiórkowski et al. 2008),[6] the Czech National Corpus,[7] and many others. Parallel corpora are also available, e.g., ParaSol.[8] However, these corpora are only available for on-line searching with specialised concordancers and not for downloading, mostly due to issues of copyright. Yet having access to the complete corpus for downloading and local data crunching is a prerequisite for many more sophisticated linguistic analyses and, especially in the case of manually annotated corpora, for training machine learning annotation software.

Probably the first publicly downloadable and manually annotated corpora were produced for the Czech language, starting with their morphosyntactically and syntactically annotated Prague Dependency Treebank (PDT) (Hajič 1998; Hajič et al. 2006). At almost the same time, the MULTEXT-East project (Erjavec 2012) released the first version of its multilingual annotated corpus. Because it only contained the novel *1984* by George Orwell in the original and its many translations, it was of somewhat limited use for linguistic investigations. Yet the project also yielded medium-sized morphosyntactic lexicons, which were the first to cover several Slavic languages.

In an effort to map this landscape, the META-NET project[9] has edited a series of (bilingual) books that cover the EU languages and give the landscape of their language resources and technologies in the digital age.[10] According to the series, the resources and technologies available for the Slavic languages are still considered to be "fragmentary" or "weak." The only exception here is the Czech language, which has a long tradition in computational linguistics and has also substantially benefited from the country's membership in the EU. Over the years much has been invested in building corpora and tools for its processing. Although not as vigorous as for Czech, other Slavic languages also have a long tradition in computational linguistics, where most of the research initially concentrated on producing inflectional lexica for the languages, e.g., for Bulgarian (Paskaleva et al. 1993) or Polish (Vetulani et al. 1998).

10 http://www.meta-net.eu/whitepapers/key-results-and-cross-language-comparison

The situation, with some corpora available for on-line exploration and a few for downloading, persisted well into the 21st century, when it slowly began to change. It became increasingly obvious that producing language resources the use of which is limited to their developers leads to great duplication of effort, where researchers are forced to repeat work already done by others, rather than focusing on analysis, thereby wasting time and money. Furthermore, experiments undertaken on closed resources cannot be duplicated and checked, which goes against the basic tenet of scientific research. This opening up came with the rise of Wikipedia and the Creative Commons licences and is by no means limited to language resources but affects all sciences. So, for example, in Horizon 2020 projects funded by the European Union it is mandatory for all research results as well as publications to be openly accessible. Of course, it is not only legal issues that prevent the dissemination of language resources: to be truly useful, the resources need to be stored in well-documented and standard formats, and interested researchers must be able to find them. One of the first projects to approach this wider view of accessibility was the already mentioned META-NET, which also developed META-SHARE, a system of digital repositories to provide the infrastructure for describing and documenting, storing, preserving, and making language resources publicly available in an open, user-friendly and secure way.

Of greater interest to linguists than the technologically oriented META-NET is CLARIN[11] (Common Language Resources Infrastructure), a European-wide research infrastructure centered on language but targeted towards humanities and social sciences scholars. While CLARIN has a central node, it is essentially a distributed infrastructure with centers now existing in 19 EU countries, including Bulgaria, Czech Republic, Poland, and Slovenia. National centers have, for the most part, established secure and long-term digital repositories which host various language resources for the languages of the countries, often under permissive Creative Commons licences. Of course, they also enable the depositing of new resources and allow for harvesting metadata by other research data repositories, making their holdings widely known. Furthermore, some centers also offer openly accessible Web applications and services, such as annotation toolchains, which enable linguists to annotate their own corpora using remote applications.

The other aspect of modern corpus collection activity is that social media offer unprecedented access to the language of everyday interaction. For example, in 2016 Facebook reported generating more than four million posts every minute.[12] However, apart from technical issues connected with capturing this amount of information from various social media platforms, there is the problem of variation in spelling, morphology, and syntax, because of the wide

[11] https://www.clarin.eu/

[12] http://wersm.com/how-much-data-is-generated-every-minute-on-social-media/

population from which data is drawn and the lack of gatekeepers (Selegey et al. 2016). While social media solve the problem of having access to sufficient data, the data they provide pose new problems for computational linguists.

6. Conclusions

The Slavic languages present a particular challenge to linguists of all kinds. Rich nominal morphology, free word order, and aspectual pairs can introduce challenges for both computational processing and corpus analysis. Fortunately, resources, both in the form of corpora and tools for processing them, are now becoming available for an increasing number of Slavic languages.

From its early beginnings, computational and corpus linguistics has, for all Slavic languages, significantly advanced and become more diversified, as also evidenced by regular international conferences organized in a number of Slavic countries: the TSD (Text Speech and Dialogue) conferences in the Czech republic, the RANLP (Recent Advances in Natural Language Processing) conferences in Bulgaria, the LTC (Language Technology Conference) conferences in Poland, the HLT (Human Language Technologies) conferences in Slovenia, Slovko conferences in Slovakia, etc. There is also SIGSLAV, a Special Interest Group for the Slavic languages at the ACL (Association for Computational Linguistics).

The range of issues encountered when applying corpus methods to Slavic languages is now matched by the range of approaches for dealing with them. One of the important trends of the last decade concerns the harmonization of text annotation. Even if each Slavic language has its own set of categories, the principles for representing the categories can be relatively generic, with a shared set of conventions for representing each category and for choosing the specific values of categories (Erjavec and Džeroski 2004; Nivre et al. 2016; Zeman et al., 2012), as well as for converting between the conventions (Zeman, 2008). A related important trend is the availability of models shared among Slavic languages, such as starting from a better resourced one to improve models for a lesser resourced language, for example, by adapting part-of-speech taggers (Babych and Sharoff 2016) or parsers (Agić et al. 2014).

In short, now is a good time for Slavic corpus linguistics, as more and more resources are becoming available, be it on-line searchable corpora or downloadable resources, and these often come with standardized encoding and are stored in long-term repositories. In addition, web-based tools are becoming available for the annotation and exploration of texts, not requiring the knowledge and high-end hardware often necessary to install and run such tools locally.
